adolescents; algorithm; children; chronic cough; diagnosis; dry cough; wet cough

Abstract
The current systematic review presented and discussed the most recent studies on pediatric chronic cough. In addition, the Italian Society of Pediatric Allergy and Immunology elaborated a comprehensive algorithm to guide the primary care approach to a pediatric patient with chronic cough.

Several algorithms on chronic cough management have been adopted and validated in clinical practice; however, unlike the latter, we developed an algorithm focused on pediatric age, from birth until adulthood. Based on our findings, children and adolescents with chronic cough without cough pointers can be safely managed, initially using the watchful waiting approach...
Overview

Cough is defined as “a forced expulsive maneuver, usually against a closed glottis, and is associated with a characteristic sound.” Cough is a protective physiological reflex deputed to clear secretion from the airways or remove inhaled material. As a physiological reflex, healthy children usually cough on average 11 times (range 1-34) daily. On the other hand, cough may also be the key symptom of diseases affecting the upper or lower respiratory airways, requiring prompt diagnosis and treatment. Cough may be pragmatically classified, considering its duration and characteristics. Conventionally, acute cough lasts less than 4 weeks, whereas chronic cough lasts more than 4 weeks. Cough may be wet, such as productive (associated with secretion), or dry, such as irritative. The current review aims to present and discuss recent evidence on chronic cough. This document, provided by the Italian Society of Pediatric Allergy and Immunology (SIAIP), proposes a practical algorithm to manage and improve clinical outcomes of children and adolescents with a chronic cough in clinical practice.

Pathophysiological mechanisms

Cough is a multifaceted neuromuscular phenomenon characterized by three dynamic steps: a deep inspiration, an exaggerated expiratory effort against the closed glottis, and the opening of the glottis, closure of the nasopharynx, and forced and exaggerate airflow emission through the mouth. These events are orchestrated by the sequential activation and coordination of an afferent circuit, a central processing pathway, and an efferent arm.

Cough receptors are generally in the larynx, trachea, bronchi, and pleura, and also the nose and paranasal sinuses, in the auditory canal, pericardium, esophagus, and stomach. Stimulation of these receptors may also elicit the cough. For example, the ear-cough reflex (Arnold’s reflex) is known. The application of an endogenous and/or exogenous stimulus on cough receptors, localized to vagal afferent nerve terminations in the airway’s mucosa, activates a complex neuronal response, which, via the release of numerous mediators, induces the cough neural circuits. From multiple peripheral and central sites, the afferent signal is transported to trigger both on-site and distal responses, thus activating the bronchopulmonary sensory nerve as well as peripheral and central sites in the brainstem. Herein, the afferent reflex is modulated, and an efferent response is generated to induce a neuromuscular effect involving laryngeal abductor and adductor muscle, diaphragm, muscles of the chest wall, and cervical and abdominal muscles.

Coughing is a protective reflex that removes foreign bodies entered into airways or enhances airway clearance, acting as an innate, built-in defense mechanism.

However, when it occurs chronically, cough becomes a disruptive health problem for the child/adolescent affected. Chronic cough, defined as a daily cough lasting for >4 weeks, represents a common pediatric health problem, with a prevalence of 35% in school-age children. Chronic cough may require multiple physician visits and hospitalization, with substantial implications for the child and patient’s family and a relevant burden for healthcare. Accordingly, appropriate diagnostic management has long been recognized as imperative to achieve the correct diagnosis promptly and guarantee the best possible therapy. Although cough is commonly considered to originate from the respiratory system, several extrapulmonary or systemic diseases can cause a chronic cough. This event is frequently observed in children with a nonspecific chronic cough in which, due to the lack of corresponding clinical symptoms, the risk of misdiagnosis and/or underdiagnosis is high. It reflects the importance of both a careful and a multidisciplinary assessment of the affected child/adolescent.

Herein, we performed an updated systematic review regarding the management of chronic cough in children and adolescents; a diagnostic and therapeutic algorithm of a chronic cough has also been developed to offer a practical guide for the pediatrician.
Methodology

Study design

A systematic review was performed according to the Cochrane handbook guidelines. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) Statement has been used for reporting of the systematic review, filling a 27-item checklist and a flow diagram (Figure 1).

Search strategy

A literature search was performed covering papers published from January 1, 2008 to July 31, 2019; the PubMed and Excerpta Medica Database (EMBASE) databases were systematically searched. In PubMed, the following search strategy was used: “cough” [MeSH] AND “chronic” [All Fields] AND “infant” [MeSH] OR “child” [MeSH] OR “adolescent” [MeSH] OR “children” [MeSH].

In EMBASE, the following search strategy was used: “cough”:ab,ti AND “chronic”:ab,ti AND “infant”:de OR “child”:de OR “adolescent”:de OR “children.

An additional research was conducted on the Cochrane Database of Systematic Reviews, and the references of relevant articles were further cross-checked.

Inclusion criteria

Studies were considered eligible if they showed the following characteristics: pediatric population (aged <18 years), papers published in English, year of publication (from 2008 to 2019), study design consisting of prospective or retrospective observational studies, and randomized controlled trial (RCT).

Exclusion criteria

Studies related to the adult population, non-pertinent articles, duplicates, letters, commentaries, case series including
<10 children, reviews, guidelines, and articles not written in the English language were excluded from the analysis.

**Studies selection**

Studies focusing on the definition of the disease, clinical presentation, and laboratory and instrumental investigations on children with chronic cough were selected.

Titles and abstracts of studies identified during the initial search were screened for inclusion, and papers focusing on chronic cough were included in this review. After that, the full text of all included papers was analyzed for further evaluation. The references of relevant articles were also crosschecked.

**Data extraction**

Data were independently extracted by two authors (SM and EC), and any disagreements or conflicts were discussed with other authors.

The following data were extracted for each study: authors, year of publication, the title of the study, location, the number of subjects included, the age of children, study type, number and type of included studies, aims/outcomes, results, and comments/limitations of the study.

The study characteristics are summarized in Table 1.

**Results**

**Literature findings**

The initial search identified 889 records (306 from the PubMed database and 583 from the EMBASE database) of which 104 were duplicates. One additional record was identified using the Cochrane Database of Systematic Reviews. Thirty-two studies met the inclusion criteria after abstracts and titles were evaluated. Fifteen of these studies were excluded because data were not pertinent or not relevant (Table 2); 17 studies (2 systematic reviews, 4 retrospective observational studies, 10 prospective analyses and 1 clinical trial) were judged eligible and included in the final analysis. The search results and the selection process are shown in Figure 1.

**Study characteristics**

This systematic review included 17 studies. Overall, 7337 children aged 24 months to 18 years presenting with chronic cough were included in the review. The study settings included emergency departments, pediatric departments, or outpatient clinics and services.

**Definition**

The definition of chronic cough is nonunanimous. Most of the studies defined chronic cough as a cough lasting more than three consecutive weeks. Two studies defined chronic cough as a cough of >8 weeks duration. Another study, by the age, chronic cough as a cough lasting >4 weeks in children <15 years and >8 weeks for adolescents ≥15 years. Only one study did not make the chronic cough definition explicit. More recently, according to the latest CHEST Expert Cough Panel guidelines, chronic cough has been defined as the presence of daily cough for more than 4 weeks for children aged ≤14 years.

**Clinical history and symptoms**

Chronic cough may be the expression of several diseases. Thus, the ability of the clinician to interpret the clinical history correctly, the type of cough, and the presence of other symptoms is crucial to establishing an accurate differential diagnosis.

Although none of the included studies was explicitly focused on clinical history and presentation of chronic cough in children, it has been noted that positive personal and family history of atopy and a previous history of chronic cough were commonly detected in children affected by chronic cough. Passive tobacco exposure was commonly reported in patients with chronic cough.

At the time of presentation, the average cough duration differed widely among studies, ranging from <7 days to 30.6 weeks. Running nose and nasal congestion, dry throat with foreign body sensation, and repeated clearing of the throat often accompanied chronic wet cough that aggravates when the posture is changed or in the early morning. It can signify an underlying illness, such as aspiration lung disease, cystic fibrosis, or noncystic fibrosis bronchiectasis.

Children with dry cough are more commonly aggravating or onset at night and/or early morning. Dry cough is associated with a high rate of spontaneous resolution without any therapeutic intervention.

Symptoms of post-tussive emesis, purulent nasal discharge, and postnasal drip showed a predictive value for a positive sinus X-ray (p < 0.001). Worsening cough at night and with exercise did not correlate with sinusitis underlying chronic cough. Conversely, these symptoms appeared suggestive, more commonly, of asthma and, less frequently, of gastroesophageal reflux disease (GERD).

**Etiology of chronic cough**

The etiology of chronic cough is broad and differs significantly in clinical settings. Airway hyperreactivity, GERD, and infectious diseases were reported as the most common causes underlying a positive history for chronic cough in adults.

By stratifying the pediatric population by age, a significant difference in the etiology of chronic cough appeared per the age range.

In the infant population (5 months-1 year of age), the sequence of the common causes of nonspecific chronic cough was upper airway cough syndrome (33.3%), cough...
Table 1  Characteristics of the included studies.

| 4  | Chang AB et al.12 | 2012 | A multicenter study on chronic cough in children: Burden and etiologies based on a standardized management pathway | Australia  | 346    | 4.5 years (mean age) | Prospective study | NA                         | 1. To evaluate the burden and etiologies using a standard management pathway in various settings  
2. To determine the influence of age and setting on disease burden and etiologies and etiology on disease burden | 17.6% of children had a serious underlying diagnosis (bronchiectasis, aspiration, and cystic fibrosis). PBB was more likely found in the younger children (<2 years of age); no significant difference among age range was reported for diagnosis of asthma, bronchiectasis, cough resolved without a specific diagnosis, and tracheomalacia. Moreover, 61/346 children (17.6%) reported more than one diagnosis: tracheomalacia was with PBB (n = 27), asthma with PBB (n = 13), and mycoplasma pneumoniae infection (n = 2), PBB with asthma (n = 8) and aspiration lung disease (n = 4), upper airways syndrome with asthma (n = 2) and PBB (n = 2), aspiration lung disease with bronchiectasis (n = 1), and gastroesophageal reflux disease (GERD) with PBB (n = 2) | Comments:  
1. The frequency of etiologies of chronic cough is dependent on the clinical setting and age has less influence  
2. Lack of an objective measurement of cough                                                                 |
Children with chronic cough: when is watchful waiting appropriate? Development of likelihood ratios for assessing children with chronic cough

Australia 326 <18 years Retrospective analysis NA

1. To determine how well cough pointers differentiate specific cough from nonspecific cough
2. Describe the clinical profile of children whose cough resolved without medications (spontaneous resolution)

1. significant ORs (95% CI) were found for:
   a. Wet cough: 73.7 (10–544.2)
   b. Wheeze or reversible airway obstruction 21.2 (1.3–349.8)
   c. Chest radiograph abnormality: 20.3 (1.2–335.4)
   d. For protracted bacterial bronchitis (PBB); asthma and bronchiectasis, the specificity of all pointers was high (>98%), but sensitivity was generally low other than wet cough for PBB and dry cough for asthma

2. Only two children in the spontaneously resolved group had a specific cough pointer, whereas at least one cough pointer was present in all children in the specific cough all-cause group.

Although the absence of other individual cough pointers did not change the pretest probability very much (negative LRs close to 1), the absence of all the pointers had a negative LR of 0 (95% CI: 0–0.03).

1. The definition of the duration of chronic cough is controversial (>4 weeks vs. >8 weeks).
2. The guidelines that use the shorter time frame do not advocate the use of medications for all children at that time point, assuming cough resolves spontaneously.
3. The comparative control group used for this study was non-homogeneous, and the LR values may change.
4. The data set used for this study was based mainly on a hospital cohort of young children, and thus the LRs calculated may change in primary care settings and older children.

Marseglia GL et al.

Psychogenic cough was also a common cause of chronic cough in children over 6 years of age (Table 3). By the characteristics of the cough, it has been reported that asthma, rhinosinusitis, and GERD were the most frequent causes of chronic specific cough, with an incidence of 69.82%, 4.6%, and 8.3%, respectively. The remaining 21% of patients showed noncystic fibrosis bronchiectasis, cystic fibrosis, bronchiolitis obliterans, tuberculosis, pneumonia, foreign body aspiration, hemosiderosis, and ganglioneuromas. PBB was the second most common cause of chronic wet cough, with bacterial culture positive for Hemophilus influenzae (43.2%), Streptococcus pneumoniae (23.9%), Moraxella catarrhalis (23.9%), Streptococcus pyogenes (6%), and Staphylococcus aureus (3%).

N: number.
Patients with a dry cough showed croup, tracheobronchomalacia, psychogenic cough, vascular, and airway abnormalities as the most frequent etiologies. Mycoplasma pneumoniae and Chlamydia pneumoniae were the most common post-infectious causes in patients with chronic dry cough on normal pulmonary function tests (PFTs) and chest X-rays. Moreover, two or more associated causative factors were frequently identified in children with a chronic cough in some studies. Specifically, Chang et al. found that 17.6% of children had more than one diagnosis: tracheomalacia was with PBB (n = 27), asthma with PBB (n = 13), and M. pneumoniae infection (n = 2), PBB with asthma (n = 8) and aspiration lung disease (n = 4), upper airways syndrome with asthma (n = 2) and PBB (n = 2), an aspiration lung disease with bronchiectasis (n = 1), and GERD with PBB (n = 2).12

**Laboratory and instrumental findings**

Currently, the clinical history and cough characteristics have been adopted as criteria to determine the diagnostic workup of chronic cough.

In their prospective study, Chang et al. enrolled 326 children newly referred for chronic cough and evaluated data on specific cough pointers (Boxes 1 and 2). They showed that the presence of a specific cough pointer indicating a cause of chronic cough had a sensitivity of 1.0 (95% confidence interval [CI]: 0.98–1.0), specificity of 0.95 (95% CI: 0.97–1.0), negative PV of 0.99 (95% CI: 0.89–1.0), positive likelihood ratio (LR) of 20 (95% CI: 5.18–77.21), and negative LR of 0 (95% CI: 0–0.03). Thus, those authors concluded that children with chronic cough without any cough pointers could be safely managed using the watchful waiting approach, while, in the presence of any cough pointers, children would benefit from further investigations, with an odds ratio (OR) of 5.28 (95% CI: 1.23–22.73).

When specific cough pointers (systemic and/or pulmonary cough pointers (Boxes 1 and 2) are present (high-quality evidence) and/or cough does not resolve within a specific time frame (ranging from 1 to >6 months) following the use of antibiotics (moderate-quality evidence), investigations should be undertaken to determine if an underlying lung disease or other diseases are present.9

In this regard, the most frequently performed investigations were fiberoptic bronchoscopy (FB) with bronchoalveolar lavage (BAL) and chest computed tomography (CT) scans or assessment of immunity; however, the chest radiograph remains the first line of instrumental investigation to perform in children with chronic cough. The FB was reporting up to 74% airway abnormalities, purulent bronchitis in 56% of cases, and laryngomalacia and/or tracheomalacia in 30.3% of cases. BAL, considered as the “gold standard” to identify lower airway infections, was used to detecting Haemophilus influenza (49%), S. pneumoniae (20%), M. catarrhalis (17%), and S. aureus (12%) as the most common bacteria. Chest CT scans were also reported as positive, and poor radiologic outcomes and structural airway abnormalities were more frequently occurring with longer cough duration.

A retrospective analysis, enrolling 58 pediatric patients younger than 18 years, revealed that flexible laryngoscopy, chest radiograph, and CT scan of the sinuses were also commonly performed in patients with chronic cough. Flexible laryngoscopy appeared useful both in the diagnosis

GERD, gastroesophageal reflux disease.
of upper respiratory tract affections and GERD. A chest radiograph was ordered for patients for whom the treatment failed, resulting in positive in most cases. OR for abnormal chest radiograph findings appeared significant for the diagnosis of PBB and pneumonia, showing a sensitivity of 0.20 (95% CI: 0.16–0.26), specificity of 1.0 (95% CI: 0.89-1.00), positive PV of 1.00 (95% CI: 0.92-1.0), negative PV of 0.15 (95% CI: 0.11-0.2), positive LR infinity, and negative LR of 0.8 (95% CI: 0.75-0.85) for the specific cough all-causes. CT scan of the sinuses was positive in patients with chronic nasal symptoms and chronic cough; X-ray of the sinuses was able to detect sinus abnormalities in more than half of the cases.

Although spirometry (pre- and post-ß2-agonists) is commonly performed in daily practice, literature data are lacking regarding its use in the pediatric population with chronic cough. Nevertheless, in their multicenter study, the authors revealed that spirometry showed a sensitivity of 0.03 (95% CI: 0.01-0.06), specificity of 1.0 (95% CI: 0.89-1.00), positive PV of 1.00 (95% CI: 0.92-1.0), negative PV of 0.15 (95% CI: 0.11-0.2), positive LR infinity, and negative LR of 0.8 (95% CI: 0.75-0.85) for the specific cough all-causes.

Finally, only one of the studies included in our systematic review investigated the diagnostic role of fractional exhaled nitric oxide (FeNO) in 90 children, aged 6-17 years, with chronic cough. By assuming 24 part per billion (ppb) and above values for FeNO positivity, Yildiz et al. revealed that FeNO showed a sensitivity of 0.78, a specificity of 0.92, a positive PV of 0.81, and a negative PV of 0.91, supporting its use as a quick and reliable diagnostic method in patients with chronic cough.

**Discussion**

Chronic cough, defined as the presence of daily cough for more than 4 weeks in duration, is hugely complicated to evaluate, and very often, the underlying disease remains not diagnosed, misdiagnosed, and/or inappropriately treated. After conducting an updated systematic review about the management of chronic cough in children and adolescents, the SIAIP proposed a diagnostic algorithm to offer a practical guide for the pediatrician to improve management and clinical outcomes (Figure 2). The initial assessment of chronic cough includes a detailed history and physical examination. First, obtaining a comprehensive clinical history allows the pediatrician to understand whether the patient is affected by a chronic...

Figure 2 Flow chart of chronic cough assessment for children.
cough. The definition of chronic cough is nebulous, and it varies widely among the studies.\textsuperscript{5,24} In this study, we adopted a period longer than 4 weeks as a cutoff period to define the cough as chronic. This prolonged observation period allows observing a spontaneous cough resolution for 20\% of otherwise healthy children, according to the postinfectious etiology in many children with chronic cough.\textsuperscript{5,12} Furthermore, during childhood, numerous anatomical and physiological maturation processes in the respiratory tract, nervous system, and immune response naturally occur and positively contribute to spontaneous cough resolution.\textsuperscript{27,28}

A detailed clinical history also permits to guide the workup for a specific diagnosis by the age of the child, the age at symptom onset, and the presence or absence of systemic and/or pulmonary “red flags” (Boxes 1 and 2). If the cough starts early after birth, spontaneously or acquired after prior intubation, trauma, infection, or inflammation, genetic disorders (cystic fibrosis, primary ciliary dyskinesia [Box 3]\textsuperscript{29}); immunodeficiencies; congenital anomalies (pulmonary, cardiac, and vascular abnormalities); pulmonary disorders (tracheobronchomalacia and surfactant dysfunction); and neuromuscular diseases must be clinically suspected.\textsuperscript{4} A sudden onset, a history of choking, followed by prolonged cough in a healthy child between 0 and 3 years of age, may suggest foreign body aspiration.\textsuperscript{6,30} Due to the enhanced responsiveness of the cough receptors, prolonged ciliary repair, and increased mucus secretion following infections, 28–57\% of preschool children with a previous positive history of pneumonia suffer from post-infectious cough, which is generally self-limited.\textsuperscript{31,32} The history of post-tussive vomiting and nausea, paroxysmal cough, and/or inspiratory whoop suggests that chronic cough can be caused by \textit{Bordetella pertussis}.\textsuperscript{32} The “allergic salute” and the “throat-clearing” type of cough can suggest the presence of postnasal drip, although the evidence of a relationship between postnasal drip and irritation of the larynx is lacking.\textsuperscript{33}

Attention must be paid to the occurrence of symptoms of a dry, noisy, and barking cough occurring only during the night, which in many cases suggests a functional breathing disorder (somatic or tic cough). Although some guidelines suggest that the presence or absence of nighttime cough with barking or honking characteristics should not be used to diagnose or exclude a dysfunctional cough syndrome, undoubtedly, the sudden occurrence of cough symptoms in an adolescent exclusively during the night remains suggestive of somatic or tic cough.\textsuperscript{37}

Exposure to pollution, allergen, and smoke may be a reason for chronic cough.\textsuperscript{4} The presence of comorbidities and the use of drugs must also be investigated; interstitial lung diseases can occur in patients who experience autoimmune or neoplastic diseases and/or undergo cytotoxic drugs or radiation treatment.\textsuperscript{5} Finally, the impact of cough on patients’ quality of life should also be recorded by administering validated questionnaires (e.g., Parent Cough-Specific QOL Questionnaire [PC-QOL], generic child: Pediatric QOL Inventory 4.0 [PedsQL], parent QOL questionnaires [SF-12], visual analog score [VAS], and verbal category descriptive [VCD] score), which might be helpful to stage cough and report changes in clinical symptoms.\textsuperscript{34}

Differentiating between a dry and wet cough may detect the presence or absence of cough pointers (Boxes 1 and 2) that would point to an underlying disease. At this point, a chest radiograph and, when age-appropriate, spirometry should be undertaken in the first-line assessment of children with chronic cough, since the presence of abnormalities implies the presence of disease.\textsuperscript{36}

In the absence of cough pointers, a short-term of high-dose (400 μg/d) inhaled corticosteroids (ICS), budesonide or beclomethasone, trial (2-4 weeks) in children with a chronic dry cough could provide a modest but significant benefit in cough symptoms.\textsuperscript{5,35} Among the guidelines on chronic cough, a defined period of ICS trial is not provided, ranging from at least 2 to 12 weeks.\textsuperscript{5,6,35} Probably, the authors aimed to differentiate the responders to a 2-week trial from the non-responders, requiring a more extended treatment period and eventually developing asthma.\textsuperscript{5,6,35,36} Specifically, if asthma therapy is warranted, the use of a 400 μg/d equivalent dose of budesonide (or beclomethasone) up to 2 weeks has been suggested, and a clinical reassessment after 2-3 weeks is also recommended. Cough

Chronic cough in childhood

that is unresponsive to ICS treatment should not be treated with increased doses of ICs. On the other hand, the resolution of cough with ICS therapy does not necessarily support a diagnosis of asthma, as an asthma-like transient clinical syndrome may occur post-upper respiratory tract infections (URTIs); thus, the patient should be reevaluated after treatment is stopped.6,26

A 2-4-week course of appropriate oral antibiotic guarantees a high response rate (>75%) in the resolution of chronic wet cough.6,39 The efficacy of antibiotics in chronic wet cough treatment was assessed by three RCTs, showing a clear benefit.9 However, in their systematic review, Chang et al.39 found lower-level evidence about the type and duration of antibiotics required. Amoxicillin-clavulanate appeared the most commonly used antibiotic, followed by clarithromycin, erythromycin, and cefaclor. Macrolide antibiotics are generally administered in children with pertussis.24 Other antibiotics were rarely used in chronic cough treatment.5,26 The duration of treatment ranged from 1 to 8 weeks: a 2-week course was sufficient, but when a chronic wet cough persists after 2 weeks of antibiotic treatment, an additional treatment of 2 weeks is suggested, especially if a PBB is suspected (Box 4).24 If a PBB diagnosis is confirmed, the patient should undergo bronchoalveolar lavage or sputum to differentiate “PBB without lower airway bacteria confirmation” from “PBB with lower airway bacteria confirmation,” requiring a specific therapeutic regimen.24 Children not reporting clinical improvement after 4 weeks of antibiotic treatment showed an increased risk of CT scan-diagnosed bronchiectasis that can occur with several chronic lung diseases, such as cystic fibrosis, primary ciliary dyskinesia, and also with PBB (adjusted OR: 5.9 [95% CI: 1.2-28.5]).5,41 Therefore, further investigations such as chest CT and flexible bronchoscopy should be performed to assess for an underlying disease.32

In the presence of cough pointers or persistence of cough, a referral from a primary care physician to a specialist is suggested. If systemic or pulmonary cough pointers are detected (Boxes 1 and 2), further diagnostic and therapeutic management will be guided by the clinical features and etiologic hypothesis. If no specific pointers are reported, we suggest that further investigations need to be undertaken and targeted toward the patient.

*All three of the above-reported criteria must be fulfilled.16

Complete blood count, erythrocyte sedimentation rate (ESR), C-reactive protein, and first-step immunity evaluation (immunoglobulin [Ig]A, IgM, and IgG) should be performed for cases with the most likely causes of chronic cough.38 Viruses such as *Cytomegalovirus*, *Respiratory Syncytial Virus*, and *Adenovirus*, or atypical microorganisms, including *M. pneumoniae*, *C. pneumoniae*, *B. pertussis* or *Parapertussis* can result in chronic cough. Accordingly, blood culture, serology, or polymerase chain reaction on nasopharyngeal secretions and sputum should be attempted in case of suspected infectious causes. In settings with high tuberculosis exposure or abnormal X-ray findings, appropriate tests for *Mycobacterium tuberculosis* infection are required.39,40

As conflicting findings about the relationship between chronic cough and atopy are reported, in the absence of symptoms and signs of allergy, testing for sensitization, such as skin prick test, total, and specific IgE, should not be performed.14 It has been reported that all these tests are unlikely to predict the patient’s response to treatment, and cough sensitivity in atopic children is not elevated.28

Children with a chronic wet cough should also be investigated to document the underlying causes such as cystic fibrosis.5

In patients with chronic cough reporting recurrent symptoms suggestive of sinus and nasal inflammation, an otolaryngological visit, nasal endoscopy, and sinus CT scan may be performed.39,40 On the one hand, nasal discharge and chronic cough are symptoms commonly reported in a child affected by chronic sinusitis, while, on the other hand, the evidence does not support the causeseffect relationship and reveal discordance between clinical symptoms and diagnostic tests and, consequently, the nonappropriateness of treatment options.5,41,42

Airways resistance determined by the interrupter technique and spirometry pre- and post-ß2-agonists test is useful in detecting isolated cough associated with airway hyperresponsiveness and asthma.6

A child with a chronic cough should undergo a chest radiograph. However, in the presence of chronic cough refractory to treatment in a child without a precise diagnosis, despite a normal chest X-ray, a chest CT scan should be attempted to evaluate small airway structural integrity and document lung diseases not visible on chest radiograph and, potentially, requiring FB.5,6 Other indications for FB in children affected by chronic cough are localized radiology changes, suspicion of inhaled foreign body, aspiration lung disease, or the need to perform clearance, lavage, and microbiological investigations.5 Purulent bronchitis, laryngomalacia, and tracheomalacia are frequently detected in children with a chronic wet cough by performing FB.25 Although BAL findings are widely reported and interpreted by the study authors as being consistent with infections, only a few studies have performed quantitative bacteriologic testing. Among these, prospective and retrospective studies have found clinically significant levels of both respiratory bacteria density (>10⁴ colony forming units/mL) and neutrophils assessing a persistent airways infection in children with chronic wet cough.9,40,44

The clinical usefulness of FeNO measurement in aiding diagnosis in patients with chronic cough has not yet been systematically evaluated, due to its high positive predictive

Among these, prospective and retrospective studies have found clinically significant levels of both respiratory bacteria density (>10⁴ colony forming units/mL) and neutrophils assessing a persistent airways infection in children with chronic wet cough.9,40,44

The clinical usefulness of FeNO measurement in aiding diagnosis in patients with chronic cough has not yet been systematically evaluated, due to its high positive predictive
value. However, we suggest that FeNO can be used as the second level of investigation in patients presenting with chronic cough-variant asthma.6,45,46

Despite claims to the contrary, gastroesophageal reflux appears to be a less frequent and doubtful cause of chronic cough in the pediatric population.3 Although there is a high incidence of esophageal dysmotility in patients with chronic cough, it is more likely that reflux is the effect and not the cause of chronic cough.5 For children with a chronic cough in the absence of underlying lung disease, the treatment for GERD is not suggested when clinical features of GER, such as recurrent regurgitation, dystonic neck posturing in infants, or heartburn/epigastric pain in older children, are absent. The patient should be treated following evidence-based GERD-specific guidelines55; if an acid-suppressive therapy is required, it should be administered for 4–8 weeks and, after treatment suspension, a clinical reassessment is recommended.26 Esophageal impedance 24-hour pH monitoring is the most sensitive tool for assessing all types of gastroesophageal reflux; in children aged less than 2 years, cough episodes were frequently preceded by weak acid reflux.44 Other diagnoses (Box 5) require further investigations such as laboratory tests, contrast imaging, upper gastrointestinal endoscopy, and high-resolution esophageal manometry, depending on presenting symptoms.5,47,48 Recently, a multidisciplinary “triple” endoscopy has been proposed as a useful investigative tool for patients with recalcitrant aero-digestive complaints like chronic cough.49 In their retrospective study, the authors reported that a rigid upper airway evaluation, a flexible bronchoscopy, bronchoalveolar lavage, and an endoscopy with biopsies performed by a gastroenterologist could provide more than one diagnosis, usually missed by one single procedure.49

Finally, if an extensive evaluation fails to clarify the etiology of chronic cough, somatic cough disorder such as habit cough, tic cough, and a psychogenic cough must be hypothesized, and counseling or referral to a psychologist/psychiatrist has been suggested in the diagnostic management.5,50 Although the habit cough is featured by a repetitive cough with barking or honking characteristics, and absence of symptom once asleep, these characteristics should be not used as a marker of habit cough. Similar totics, suppressibility, distractibility, suggestibility, variability, and the presence of a premonitory sensation should be taken into consideration. Moreover, by the DSM-5 classification of diseases, the authors suggest substituting the diagnostic term “tic cough” with “habit cough” and “somatic cough” with “psychogenic cough”.26

**Limitation of the study**

We developed this systematic review using a rigorous research method. However, we cannot exclude that some studies have not been included in the present manuscript.

**Conclusions**

In summary, we elaborated a comprehensive algorithm to guide a primary care approach to pediatric patients with chronic cough.

Several algorithms for the management of chronic cough have been adopted and validated in clinical practice5,6,16,20,35; however, unlike the latter, we developed an algorithm focused on the pediatric age, and, also, in accordance with the Italian National Health System, which always follows the child from birth to all life-long. Based on our findings, children with chronic cough without cough pointers can be safely managed, initially, using the watchful waiting approach and, successively, starting empirical treatment based on cough characteristics. Unlike other algorithms that suggest laboratory and instrumental investigations as a first step5,6,16,20,35 we highlighted the importance of a “wait and see” approach, consisting of parental reassurance and close clinical observation, also due to interprofessional collaboration and communication between general practitioners and specialists that guarantee better patient management, appropriate prescription behavior, and improved patient outcome. Moreover, the neonatal screening program, provided by the Italian National Health System, which intercepts several diseases precociously allowing to treat
them in a very early stage, helps and supports a “wait and see” approach.

Conversely, in the presence of cough pointers or persistence of cough, the patient should be tested and treated by a specialist. Further investigations and treatments will be based on cough etiology, aiming to intercept the underlying disease, prevent potentially irreversible tissue damage, improve the general health of patients affected by chronic cough, as well as the quality of life of patients and its family.

Further high-quality RCTs are needed to validate this algorithm’s performance in real-life clinical practice.
